22 **Abstract**  
23

24 Al-Fe-bearing protoenstatite was discovered in Oregon sunstones with unusual pleochroic  
25 / dichroic red to green coloration using high-resolution transmission electron microscopy  
26 (HRTEM) and X-ray energy dispersive spectroscopy (EDS). The empirical formula calculated  
27 on the basis of 6 O *apfu* is  $(\text{Mg}_{1.17}\text{Fe}_{0.43}\text{Al}_{0.26}\text{Ca}_{0.03}\text{Na}_{0.10}\text{Ti}_{0.01})_{\Sigma 2.00}(\text{Si}_{1.83}\text{Al}_{0.17})_{\Sigma 2.00}\text{O}_6$ . The  
28 protoenstatite has a space group of *Pbcn*; its unit-cell parameters refined from selected-area  
29 electron diffraction patterns are  $a = 9.25(1) \text{ \AA}$ ,  $b = 8.78(1) \text{ \AA}$ , and  $c = 5.32(1) \text{ \AA}$ . The esds on the  
30 cell parameters were determined based on electron diffraction patterns from the coexisting native copper  
31 inclusion and the host labradorite with known cell parameters. Protoenstatite nanocrystals are  
32 quenchable to low temperature. The crystallographically-oriented nanocrystals of protoenstatite  
33 and clinoenstatite in association with copper nanocrystals are responsible for the unusual green  
34 and “watermelon” coloration of the labradorite gemstone.

38

## 39 **Introduction**

40 Enstatite,  $\text{Mg}_2\text{Si}_2\text{O}_6$ , with a space group of *Pbca*, has several polymorphic counterparts  
41 including clinoenstatite (*P2<sub>1</sub>/c*), high-temperature clinoenstatite (*C2/c*), high-pressure  
42 clinoenstatite (*C2/c*), protoenstatite (*Pbcn*), and high-pressure protoenstatite (*P2<sub>1</sub>cn*) (Cameron  
43 and Papike 1981; Tribaudino et al., 2002; Angel et al., 1992; Yang et al., 1999). Protoenstatite is  
44 reported to be a high temperature form that cannot be quenched to room temperature (Cameron  
45 and Papike 1981; Tribaudino et al., 2002). Protoenstatite would transform to enstatite or  
46 clinoenstatite at low temperature based on the results of synthetic protoenstatite (Cameron and  
47 Papike, 1981; Chen and Prensall, 1975; Smith, 1969; Smyth, 1974). However, a synthetic Li-  
48 Sc-bearing protoenstatite with smaller cations of Li and Sc in octahedral sites is quenchable at  
49 low temperature (Smyth and Ito, 1975). It is reported that protoenstatite was a precursor of  
50 clinoenstatite in some Mg-rich basalts (Dallwitz et al., 1966; Shiraki et al., 1980) and even in  
51 star dusts (Schmitz and Brenker, 2008). In this letter, results from electron diffraction and high-  
52 resolution TEM (HRTEM) imaging are presented. The mineral and name have been approved  
53 by Commission on New Minerals, Nomenclature and Classification (CNMNC) of the  
54 International Mineralogical Association (IMA 2016-117). Two characterized specimens  
55 (catalogue numbers UWGM 3538 and UWGM 3539) are deposited in the collections of the  
56 Geology Museum, Department of Geoscience, University of Wisconsin-Madison (1215 West  
57 Dayton Street, Madison, WI 53706, USA).

58

## 59 **Samples and Experimental Methods**

60 Protoenstatite occurs as precipitates associated with copper nanocrystals in gem-quality  
61 labradorite phenocrysts (Oregon sunstones) from Dust Devil Mine, Lake County, Oregon

62 (Figures 1 and 2). The site is located in the Rabbit Basin within the Oregon high desert. The host  
63 rock is a mid-Miocene basalt (Johnson et al., 1991; Peterson, 1972). The phenocrysts are  
64 generally tabular plates and large laths ranging from ~1 cm in the greatest dimension to lathes  
65 8.3 cm long, 2.6 cm wide and 1 cm thick (Hofmeister and Rossman, 1985; Johnson et al., 1991;  
66 Peterson, 1972; Stewart et al. 1966). Protoenstatite was discovered in the green part of the  
67 “watermelon” variety that possesses a clear rim and a core of transparent red surrounded by a  
68 clear vibrant green border that can only be seen in certain orientations (Figure 1). Some carved  
69 or faceted red, green and watermelon Oregon sunstones are illustrated in supplementary material  
70 (Fig. S1).

71

72 The “watermelon” sunstones exhibit pleochroism and dichroism. Color and schiller are  
73 always localized in the cores of the phenocrysts where the native copper micro- or nano-platelets  
74 that populate the interior are exsolved clusters of crystals. They are most commonly exsolved  
75 parallel to the feldspar crystal plane (010), but also (001) (Hofmeister and Rossman, 1985). This  
76 dichroism is exhibited in hand samples of “watermelon” sunstones. The crystals exhibit  
77 dichroism with a clear red when oriented approximately parallel to the feldspar (001) plane, and  
78 both red and green are seen when oriented in [100] and [010] directions (Figures 1). The parts  
79 with green color also exhibit a brownish red / green pleochroism under a plane polarized light  
80 (Figure 2). The same phenomenon was observed by Johnson et al. (1991). Pleochroism appears  
81 to become stronger in deeply colored specimens. By contrast, the clear rim does not show  
82 pleochroism.

83 Because protoenstatite occurs as nano-inclusions in gem-quality “watermelon” sunstones,

84 ion-milled TEM specimens (on Mo grids) were used for the mineralogical characterization using  
85 transmission electron microscope associated with an X-ray energy-dispersive spectroscopy (EDS)  
86 system. HRTEM imaging, X-ray EDS and selected-area electron diffraction (SAED) analyses  
87 were carried out using a Philips CM200-UT microscope equipped with GE light element energy-  
88 dispersive X-ray EDS at the Materials Science Center, University of Wisconsin-Madison, and  
89 operated at 200 kV. Chemical analyses were obtained using the EDS (spot size 5 with a beam  
90 diameter of ~50 nm). Quantitative EDS results were obtained using experimentally determined  
91 k-factors from standards of albite, forsterite, anorthite, orthoclase, labradorite, fayalite, and  
92 titanite. The same method was used for characterizing nanocrystals of luogufengite, Al-bearing  $\epsilon$ -  
93  $\text{Fe}_2\text{O}_3$ , (Xu et al., 2017).

94  
95

## 96 **Results and Discussion**

97 TEM images show the protoenstatite nano-precipitates within labradorite together with  
98 native copper nanocrystals (Fig. 3). SAED patterns reveal their proto-pyroxene structure with the  
99 space group *Pbcn* (Fig. 4). X-ray EDS analysis confirms their pyroxene stoichiometry (Fig. 5,  
100 Table 1). The empirical formula calculated on the basis of 6 O *apfu* is  
101  $(\text{Mg}_{1.17}\text{Fe}_{0.43}\text{Al}_{0.26}\text{Ca}_{0.03}\text{Na}_{0.10}\text{Ti}_{0.01})_{\Sigma 2.00}(\text{Si}_{1.83}\text{Al}_{0.17})_{\Sigma 2.00}\text{O}_6$ . HRTEM image shows (100) lattice  
102 fringes with a periodicity of 9.25 Å corresponding to periodic changes of skews of octahedral  
103 layers along the *a*-axis (Fig. 6). The observed HRTEM image matches protoenstatite structure,  
104 instead of enstatite or clinoenstatite (See Table 2 for comparison).

105 Unit cell parameters were determined based on diffraction patterns from the  
106 protoenstatite nanocrystals. Neighbouring copper nanocrystals and the labradorite host were used  
107 as internal standards. Unit cell parameters of the labradorite with a very similar composition

108 (from Lake County, Oregon) are from Wenk et al. (1980). The measured unit-cell parameters are  
109  $a = 9.25(1) \text{ \AA}$ ,  $b = 8.78(1) \text{ \AA}$ , and  $c = 5.32(1) \text{ \AA}$ . Calculated density of protoenstatite is 3.30  
110  $\text{g}\cdot\text{cm}^{-3}$ . Calculated powder X-ray diffraction peaks are listed in Supplementary Material (Table  
111 S1). Comparison among the enstatite polymorphs with pyroxene structures is listed in table 2.

112 The crystals larger than  $\sim 200 \text{ nm}$  transformed into clinoenstatite with a high density of  
113 stacking faults (Fig. S5), which is very similar to the observed microstructures in a fast-cooled  
114 protoenstatite (Ijima and Buseck, 1975). Cooling of the lava resulted in transformations from  
115 protoenstatite to clinoenstatite with a high density of stacking faults in large protoenstatite  
116 crystals ( $> 200 \text{ nm}$ ), whereas small protoenstatite crystals ( $< 200 \text{ nm}$ ) are preserved in the host  
117 labradorite phenocrysts. The Al-bearing protoenstatite nanocrystals with large surface areas may  
118 lower the phase transformation temperature and stabilize the structure at low temperature.  
119 Similar phenomenon occurs in hematite-luogufengite system (Lee and Xu, 2016). It is also  
120 reported that protoenstatite nanocrystals with a large surface area of  $615 \text{ m}^2/\text{g}$ , synthesized using  
121 sol-gel and freeze-dry methods, can be quenched to room temperature (Jones et al, 1999).  
122 Protoenstatite nanocrystals were synthesized by sol-gel method at  $800 \text{ }^\circ\text{C}$  (Jones et al, 1999),  
123 which is lower than the reported phase transition temperature ( $\sim 1000 \text{ }^\circ\text{C}$ ).

124

## 125 **Implications**

126 The labradorite ( $\text{An}_{65}$ ) phenocrysts are very homogeneous in composition (Stewart et al.,  
127 1966; Wenk et al., 1980). We infer that the cores of “watermelon” crystals formed at early stages  
128 of magma chamber formation at high P-T conditions. The clear phenocryst rims without any  
129 precipitates suggest that they formed at a late stage under different conditions. Crystallization of  
130 protoenstatite and associated native copper might happen also at a late stage but before magma

131 eruption. The collective effect of the oriented crystals of protoenstatite and clinoenstatite results  
132 in the vibrant green colour of “watermelon” sunstones. These results may help understand and  
133 determine size-dependent stability of these minerals. We agree that the phenocrysts experienced  
134 a thermal shock due to the rapid rising and quenching of the crystals (Hofmeister and Rossman  
135 1985). This thermal shock origin can explain why the labradorite crystals without schiller and  
136 colors are all cracked. The colored sunstones are thus thermal shock resistant. Like a “single  
137 crystal concrete,” their nano-inclusions of protoenstatite and Cu probably serve as cushion to  
138 absorb the thermal shock due to metallic / plastic behavior of the Cu nanocrystals. This observed  
139 texture may inspire the design of new crystalline materials that have strengths to resist thermal  
140 shock while being optically clear and colorful.

141

## 142 **ACKNOWLEDGMENTS**

143 Authors thank Dr. Hongwu Xu and two anonymous reviewers for many constructive  
144 suggestions and comments. This study was supported by NSF (EAR-0810150, EAR-1530614)  
145 and the NASA Astrobiology Institute (N07-5489). Samples were collected by G. Farfan, C.  
146 Peralta and the Dust Devil Mining Company.

## Figures and Captions

201

202

203 Figure 1. A gem-quality “watermelon” Oregon sunstone looked down along the normal of (001)

204 (a), and along *b*-axis (b). Note the exceptionally clear rim, along with the zoning of colors. The

205 green border becomes brownish red when looked down along the normal of (001) (a). Top up-

206 right inset shows the detail of the red to green transition from a polished sample (~ 4 mm thick)

207 (b). Dark areas are due to uneven surfaces that bend the transmitted light away. Another

208 “watermelon” sunstone (c) with a clear rim looked down along ~*b*-axis under a transmitted light

209 from bottom (left). Linear features with dark color in red core and green board are microplates of

210 native Cu.

211

212 Figure 2: Transmitted light photomicrographs of a polished sunstone crystal (~ 5 mm thickness)  
213 from the green border part show pleochroism (light brown to pale green). The cleavage plane  
214 (001) is perpendicular to the light. Some inclusions appear as linear features distributed along the  
215 (010) plane of labradorite. The appearance of the inclusions is much larger than their actual sizes  
216 due to the strain existing between the nanocrystals and the host labradorite.

217

218

219 Figure 3. Dark-field TEM image (a) and bright-field TEM image (b) showing two protoenstatite  
220 (PEN) nanocrystals together with native copper nanocrystals (Cu) within labradorite.

221

222 Figure 4. SAED patterns of protoenstatite nanocrystals shown in Figure 1 along  $\sim [010]$  zone-  
223 axis (a) and along  $[012]$  zone-axis (b). The very strong 002 diffraction spot in the SAED pattern  
224 (a) is due to very small excitation error (or diffraction error) for 200, which means that the  
225 crystal is very close to two-beam condition. Weak  $h00$  ( $h = 2n+1$ ) reflections that violate the 2-  
226 fold screw axis symmetry result from multiple diffraction that is common in electron diffraction,  
227 especially from thick specimens. The  $h00$  ( $h = 2n+1$ ) reflections are extinct from a smaller and  
228 thinner crystal (b). The multiple diffraction effect is not obvious here. The SAED patterns  
229 confirm the  $Pbcn$  symmetry.
